Abstract

In recent years, due to increased air pollution, bronze objects exposed in urban areas suffer continuous degradation. Therefore, it is important to find efficient methods to protect them against corrosion. The present work aims to investigate the corrosion resistance of various artificial patinas currently used in bronze sculpture. Once formed, the patina is relatively stable and acts as a protective coating of the bronze object under many exposure conditions. The protective effect of different artificial patinas was comparatively investigated by electrochemical and non-electrochemical methods.

Keywords: bronze; corrosion; patina; polarization curves.

Introduction

A bronze surface exposed to the atmosphere forms a thin layer of corrosion products and that layer, formed naturally, is called noble patina [1 - 5]. The final quality of the patina varies depending on the composition of the alloy and the environmental conditions it develops in. From a chemical point of view that layer can be described as a hydrated copper oxide stabilized on a copper oxide substrate [1, 6 - 8].

Many factors influence the initial development of the patina, some of them may be active throughout the life of a work of art. The surface and the color of a work of art show evidence of prolonged contact with pollutants in the atmosphere. The most damaging are chlorides (sodium chloride, which allows the development of copper chloride), sulfates and oxides, especially sulfur dioxide [8 - 12].

A common method to protect bronze surfaces is to cover them with an artificial patina, by using chemical reagents or by electrochemical methods [13 - 14]. Artificial patinas offer surface protection against corrosion and it also has an aesthetic value.

The first evidence of the use of artificial patina dates back to antiquity. Mirrors dating from the Bronze Age were discovered in China which indicated that there are chemicals deliberately placed on the surface of bronze [15].

That shows that from ancient times artists wanted that the works of art made by them be durable and have outstanding aesthetic properties. Therefore, finding artificial patinas to protect works of art made of bronze is a current concern.

The main objective of this paper is to study the protective effect of various artificial patinas deliberately produced by sculptors on bronze. The study was conducted under conditions that simulate acid rain.

**Experimental**

To conduct the electrochemical studies, a contemporary bronze object was selected, whose chemical composition, displayed in Table 1, is close to the bronze used by sculptors in the early 20th century.

Figure 1 presents the microscopic structures of electrodes, magnified at 100X, 200X, 500X, which were subjected to accelerated corrosion in an environment that simulated acid rain.

For the microscopic study the electrodes were polished on the sample polishing machine with alumina paste, after which the surface was washed with ammonia cupric chloride. The study of the surface was done by optical microscopy (OLIMPIUS GS 51).

The images in Figure 1 display the dendritic segregation of the α solid solution and interdendritic segregations of eutectoid α + δ in small quantities. The eutectoid α + δ is formed in a Cu - Sn alloy and results from the decomposition of phase γ at a temperature of 520°C (see the equilibrium diagram Cu - Sn). According to the picture displayed in the Metallurgic Atlas, the structure is the one specific for cast bronze.

The electrochemical measurements were performed on a PC – controlled electrochemical analyzer AUTOLAB – PGSTAT 10 (Eco Chemie BV, Utrecht, The Netherlands) using a three electrodes cell containing a working electrode, a saturated calomel electrode (ECS) as reference electrode and a platinum counter electrode.

The working electrodes made of bronze CuSn8, cylindrical, were placed in a PVC tube, while the sealing was assured with epoxy resin.
A STUDY ON THE CORROSION RESISTANCE OF BRONZES COVERED WITH ARTIFICIAL PATINA

a,b,c – 100X; d,e,f – 200X; g,h,i– 500X
Thus, the surface of the electrode exposed to the solution was circular, with a surface $S = 1.76 \text{ cm}^2$. For the electrical contact a metal rod was attached (Fig. 2).

The electrolyte solution for corrosion measurements containing $0.2 \text{ g/L Na}_2\text{SO}_4 + 0.2 \text{ g/L NaHCO}_3$ (pH = 5).

The study was conducted on three electrodes. The electrodes were covered with an artificial patina: electrode (1) was treated with flowers of sulphur, electrode (2) was treated with a solution containing iron ions and nitric acid and electrode (3), with iron ions and copper sulfate.

**Results and discussion**

The experiments started by measuring the potential of the working electrode in an open circuit for a period of 3600 seconds, the records being presented in Figure 3.

As shown in the figure 3, for all studied electrodes, in the first minutes of immersion in the corrosive solution, the potential in open circuit evolves towards more positive values, reaching a stationary value after approx. 35 minutes.

![Fig.3. Time variations of the open circuit potential of the bronze electrodes immersed in 0.2 g/L Na_2SO_4 + 0.2 g/L NaHCO_3 (pH = 5)](image)
This behavior can be attributed to the chemisorptions of oxygen on the surface of the dissolved bronze, along with the formation of surface oxide layers, hydrosulphate and/or hydroxycarbonate [17].

It can be noticed that the open circuit potentials of the coated electrodes (2) and (3) are more positive than that of bare bronze, suggesting an interaction of the patina with the anodic process (metal dissolution), while the open circuit potential of electrode (1) is more negative than that of uncovered bronze, suggesting a possible interaction with the cathodic process (reduction of O$_2$).

To determine the polarization resistance of the electrodes, linear polarization curves were recorded, in the potential domain of ± 20 mV around the value of the open circuit potential (ocp) (Fig. 4). The polarization resistance values for each electrode, calculated as the inverse of the slope of each curve, are shown in Table 2.

The highest value for $R_p$ was observed in the case of the electrode (2), treated with a solution containing iron ions and nitric acid.

To determine the kinetic parameters of the corrosion process, polarization curves were recorded in the potential range of ± 200 mV vs. ocp (Fig. 5).

As shown in Table 3, the coated electrode 3 is the less resistant to corrosion and it presents accelerated corrosion in comparison with bare bronze. Treatment 2 seems to be the best among the treatments tested. However, the amelioration of the corrosion rate is not significant. That is due to the fact that the patina layer is not continuous, as can be seen in Figure 6.

Fig. 5. The polarization curves (± 200 mV vs. ocp) for the studied electrodes immersed in 0.2 g/L Na_2SO_4 + 0.2 g/L NaHCO_3 (pH = 5)

A STUDY ON THE CORROSION RESISTANCE OF BRONZES COVERED WITH ARTIFICIAL PATINA

Conclusions

Accelerated corrosion tests in an environment that simulated acid rain on contemporary bronze covered with different artificial patinas, revealed that the investigated patinas have a limited protection effect on bronze corrosion. The differences between their corrosion rate and that of uncovered bronze are not important because the patina layers were not enough compact and uniform.
